HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
A comparison of some methods for clustering of variables of mixed types

We compare several old and recent methods for clustering a set of qualitative and quantitative variables.

Keywords: clustering of variables, mixed data, PCA, RV coefficient

The simultaneous treatment of a mixture of $J$ quantitative variables $x_j$ and $Q$ qualitative variables $\tilde{x}_q$ with $m_q$ categories, whether in factorial analysis or clustering, is often based on the determination of one or more global or local (i.e. per class) synthetic variables optimizing the following criterion introduced in 1977 by Tenenhaus [6], reused by Escofier (1979), then Saporta [5], Kiers (1991) under the name of PCAMIX, and Pagès (2004):

$$\max_c \left( \sum_{j=1}^{J} r^2 (c, x_j) + \sum_{q=1}^{Q} \eta^2 (c, \tilde{x}_q) \right)$$

(1)

where $r^2$ is the squared Pearson correlation coefficient between two quantitative variables and $\eta^2$ the squared correlation ratio between a quantitative and a qualitative variable. Both coefficients are equal to the proportion of variance of a dependent variable explained by an independent one.

The ClustOfVar algorithm [1] uses criterion (1) to perform a clustering of a set of variables of different nature around latent components in each group, extending the method of Vigneau and Qannari [7] introduced for exclusively quantitative variables. Clustering variables around components is an interesting alternative to direct algorithms that start from the table of similarities, dissimilarities or distances between all variables, because it simultaneously optimizes the clustering and the representation of classes by a component as in a clusterwise approach.

A key issue is to use consistent and comparable similarity measures in the three cases: a pair of quantitative variables, a pair of categorical variables and a pair consisting in a quantitative variable and a categorical one. The association coefficients $r^2$ and $\eta^2$ are in common use, while various solutions have been proposed for the case of two categorical variables: chi-squared and its derivatives such as $T^2$, which is the square of the Tschuprow coefficient, or the largest eigenvalue of the Correspondence Analysis matrix derived from the cross-tabulation of two categorical variables [1].
Coefficients associated with categorical variables are not, however, comparable with each other or with $r^2$ because their distributions depend on their number of categories. In criterion (1) a qualitative variable plays a greater role the higher its number of categories $m_q$. The Escoufier $RV$ coefficients [4] between tables generated by each quantitative variable and tables of indicators of the categories of the qualitative variables make it possible to define Euclidean similarities equal, according to the cases, to $r^2, \frac{n^2}{\sqrt{m_q-1}}$ or $T^2$ [3].

We can then perform hierarchical clustering with Ward’s algorithm or $k$-means partitioning, either directly on the similarity matrix, or on the coordinates obtained by the Torgerson formula. This elegant but somewhat forgotten solution still suffers from a flaw: dividing by the square root of the degree of freedom does not completely correct the effect of the number of categories. For this, it may be wise to use as dissimilarity the $p$-value of the independence test in the spirit of the likelihood linkage algorithm [2]. However Euclidean properties are lost.

In addition, when the number of observations is very large, all $p$-values are close to zero (paradox of large samples) and are no longer usable. We propose to replace them by the corresponding fractiles of the standard normal distribution in the spirit of the test values used in the SPAD software. The larger the fractile, the greater the association between two variables. These different approaches are compared on real data sets.
